Cloud features and zonal wind measurements of Saturn’s atmosphere as observed by Cassini/VIMS

D. S. Choi,1 A. P. Showman,1 and R. H. Brown1

Received 21 August 2008; revised 15 January 2009; accepted 11 February 2009; published 16 April 2009.

[1] We present an analysis of data about Saturn’s atmosphere from Cassini’s Visual and Infrared Mapping Spectrometer (VIMS), focusing on the meteorology of the features seen in the 5 μm spectral window. We present VIMS mosaics and discuss the morphology and general characteristics of the features backlit by Saturn’s thermal emission. We have also constructed a zonal wind profile from VIMS feature tracking observation sequences using an automated cloud feature tracker. Comparison with previously constructed profiles from Voyager and Cassini imaging data reveals broad similarities, suggesting minimal vertical shear of the zonal wind. However, areas of apparent wind shear are present in the VIMS zonal wind profile at jet stream cores. In particular, our analysis shows that the equatorial jet reaches speeds exceeding 450 m s⁻¹, similar to speeds obtained during the Voyager era. This suggests that recent inferences of relatively slower jet speeds of ~275–375 m s⁻¹ are confined to the upper troposphere and that the deep (~1 bar) jet has not experienced a significant slowdown. Our measurements of the numerous, spotted features seen in the VIMS mosaics reveals that most of these features have diameters less than 1000 km and reside in confined zonal bands between jet stream cores. We propose that these spot features are vortices and that VIMS and Imaging Science Subsystem are sensing the same vortices at two different pressure levels. The local structure at the zonal jet streams remains complex, as VIMS may be sensing cloud features that are deeper than the NH₃ cloud deck.

1. Introduction

[2] Saturn’s atmosphere has a reputation for being bland and unremarkable, especially when compared against Jupiter’s colorful bands and vortices. A strongly scattering haze confined to the higher altitudes of the atmosphere is mostly responsible for obscuring the activity occurring at depth. Recent imaging results from Cassini have revealed this activity: dozens of compact, dark spots (likely anticyclonic vortices) populate Saturn’s midlatitudes [Porco et al., 2005], and vigorous storms with inferred lightning discharges imply energetic updrafts in tandem with strong precipitation [Dyudina et al., 2007]. Vasavada et al. [2006] describe tilted cloud streaks, abundant vortices, patchy bright clouds, and dark bands coincident with the location of zonal jet streams throughout Saturn’s southern hemisphere. Their observed vortices had lifetimes on the timescale of several to hundreds of days, demonstrating the activity of the atmosphere. Though Cassini’s Imaging Science Subsystem (ISS) [Porco et al., 2004] was not yet able to fully observe the northern hemisphere, Vasavada et al. [2006] noted similarities between both hemispheres on the basis of previous studies from Voyager [Smith et al., 1981, 1982; Sromovsky et al., 1983].

[3] Saturn’s zonal wind profile, especially at its equatorial region, has been the subject of much discussion. Voyager imaging data indicated that the broad equatorial jet flowed as fast as 470 m s⁻¹ at its peak [Sánchez-Lavega et al., 2000]. However, Hubble Space Telescope (HST) observations of the jet from 1996–2002 showed evidence for a dramatic slowdown in the velocity of the jet by almost a factor of 2 [Sánchez-Lavega et al., 2003] over a broad (~30°) span of latitudes. Explanations for the slowdown include a true decrease in the speed of the jet or that HST observed higher-altitude clouds that would flow at slower speeds [Flasar et al., 2005]. Sayanagi and Showman [2007] performed numerical experiments that suggested that a combination of both is necessary to account for the apparent slowdown. Recent results from the Cassini orbiter made by Porco et al. [2005] have bridged the Voyager and HST measurements, as they supply a measurement of winds near 375 m s⁻¹ at the equator using a near-infrared continuum band that samples deeper in the atmosphere than the HST measurements.

[4] With the arrival of Cassini in 2004, planetary scientists gained the capability of using an imaging spectrometer to assess the characteristics of the Saturnian atmosphere.

The Visual and Infrared Mapping Spectrometer (VIMS) instrument is a 64 × 64 pixel spectrograph capable of near-simultaneous observations of a target from 0.3–5 μm. VIMS is a hybrid instrument combining a slit-scanning visible spectrometer [Capaccioni et al., 1998] with a spot-scanning near-infrared spectrometer [Brown et al., 2004]. For this paper, we focus primarily on data in the near infrared, specifically at 5 μm. We utilize this spectral window because of its potential to probe deeper layers of the atmosphere. In 5 μm, Saturn’s thermal emission can be directly observed, and Saturn’s atmospheric cloud features are seen “backlit” against the infrared emission, indicating that these features are located anywhere in between the top of the atmosphere and the 5 μm emission level. Bjoraker et al. [2007] estimates the 5 μm emission layer at around 5 bars, which is below the estimated altitude (1–2 bars) for the cloud tops seen in ISS images observing reflected solar radiation.

Baines et al. [2005b] conducted an initial study of results from the first year of data from the Cassini VIMS instrument. Although their initial reports focused mostly on constraining atmospheric compositions, the reports made the important initial discovery of meteorological features seen in Saturn’s atmosphere in the 5 μm spectral region. Momary et al. [2006] characterize these features, some of which have peculiar descriptions: certain features in the northern high latitudes are “donut-like” and are presumably vortices with a relatively cloudless inner core. Furthermore, a train of cloud clearings arranged like a “string of pearls” inhabits the northern midlatitudes. They determine that these clearings are quasi-evenly spaced with a near 4:1 flux contrast ratio and estimate their altitude to be near the 2.5 bar level. On a global scale, Momary et al. [2007] report a pronounced asymmetry in the hemispherical flux emitted by Saturn. The northern hemisphere emits nearly twice the flux of the southern hemisphere, possibly indicative of strong seasonal changes in the formation and dissipation of aerosols in the upper troposphere (~300 mbar) of Saturn.

For this paper, we have undertaken an analysis of VIMS data of the Saturnian atmosphere from Cassini up to 31 March 2007. We present descriptions of the basic morphology of the features seen in the VIMS imagery, and provide statistics on the latitudinal and size distribution of these features. We also perform a comparative analysis of the features seen in VIMS and ISS mosaics. We have adapted an automated cloud feature tracking algorithm to construct the zonal wind profile of Saturn’s atmosphere from VIMS data. We compare this profile to previously derived profiles to estimate the vertical wind shear.

2. Data and Methodology

2.1. Data Sets and Common Procedures

We obtained VIMS datacubes from the NASA PDS Imaging Node, and restricted our analysis to data sets of Saturn’s atmosphere that either (1) attempted feature tracking by repeatedly observing the same absolute frame relative to System III longitude or (2) monitored the overall state of Saturn’s atmosphere via full-disk mosaics over a Saturnian day. All of the data that we analyzed is included as Table 1. We perform the standard VIMS data processing pipeline (e.g., removing cosmic ray hits, dividing by a prelaunch flat field, dividing by a solar spectrum, etc.) using software provided by the VIMS team. Barnes et al. [2007] discusses this pipeline further. We used the ISIS (Integrated Software for Imagers and Spectrometers) software suite [Gaddis et al., 1997] for further data reduction and processing, which we discuss in the following paragraphs.

All of the VIMS datacubes in this study were prepared for analysis by first coadding the five longest-wavelength channels in the data cube (5.057–5.122 μm) and omitting the remainder. With ISIS, we reprojected the image into a rectangular (simple cylindrical) projection, and used kernels provided by the Navigational and Ancillary Information Facility (NAIF) at the Jet Propulsion Laboratory for absolute image navigation and orientation. Our reprojected images that were used for both mosaic construction and feature tracking are oversampled at 0.1° pixel^{-1} by utilizing a bicubic interpolation scheme supplied with ISIS. (1° on Saturn is ~1000 km.) Typical VIMS images have a native resolution of about 0.25° pixel^{-1} on Saturn, though this resolution strongly depends on the observation geometry and range from the target. Typical spacecraft ranges from Saturn during observations were ~9 × 10^3 km, though these ranges sometimes varied by as much as 50%.

A primary source of uncertainty in this paper is errors in the pointing knowledge of the spacecraft. Though the kernels provided by NAIF are carefully crafted, some uncertainty in the absolute location of where the spacecraft is pointing and the geographical location of the target is inevitable. We were unable to perform any manual correction to the pointing knowledge of the images via limb-fitting or other methods during the processing pipeline. We estimate the uncertainty in the absolute location of the cloud features to be 1–2° J. Barnes, personal communication, 2008). However, the relative uncertainty in location between pixels is much smaller. Thus, our measurements of lengths and velocities, which are more dependent on relative uncertainty, do not degrade much in quality because of the small, nonzero, absolute uncertainty.

2.2. Mosaics

We created global-scale mosaics of Saturn’s atmosphere using VIMS data in order to characterize the frequency and size distribution of observed cloud features. In order to enhance the visible features and maximize the data
return from the VIMS instrument, we implemented an unsharp mask procedure described by Le Mouëlic et al. [2007]. This technique simply subtracts a percentage of a low-pass-filtered version of the original image from the original data. The resulting mosaics offer enhanced contrast and improved visibility for the backlit features. No special processing was performed to mitigate image seams.

We constructed two near-complete mosaics of Saturn’s southern hemisphere, as Cassini observed the southern hemisphere twice over a period of nearly two weeks in December 2006. During both observation sequences, the spacecraft acquired data by imaging the hemisphere in a 3 × 3 grid (with one corner absent) at regular intervals during a Saturnian rotation. The entire southern hemisphere is observed up to 80°S, though some gaps in the coverage are present. We also constructed one mosaic of the northern hemisphere up to 60°N from observations in September 2006. This mosaic has relatively lower spatial resolution from unfavorable orbital and observational geometry. Other observational sequences that covered the northern hemisphere with improved resolution during the Cassini mission in the publicly available data sets were insufficient in global coverage or otherwise had unfavorable viewing conditions.

2.3. Cloud Feature Census

For the mosaics presented in this paper, we performed a statistical assessment of the population and characteristics of the features seen in Saturn’s atmosphere. We limit our analysis to spot-like cloud features that are dark, compact, and ellipsoidal. These features are ubiquitous in the midlatitudes and higher latitudes of the atmosphere. These features may be vortices, though we cannot explicitly confirm this because we currently are incapable of measuring local wind velocities within these structures. Furthermore, there are many complex and ambiguous structures where spots appear to be merging, shearing apart, or otherwise deforming. We elect to exclude these structures in our analysis in order to establish a lower bound in cloud feature population. To assess the statistics of the cloud features seen in 5 μm, we measured the central locations of these features to determine their latitudinal distribution. To measure lengths, we used the measuring tool in the ISIS software package to measure both the longitudinal and latitudinal span of these spots. This software tool is capable of precise, subpixel measurements, but we must be careful with their interpretation as we are examining oversampled and interpolated mosaics. We estimate the uncertainty in the measurement of feature lengths to be at the level of 1 native resolution pixel (~250 km).

2.4. Automated Feature Tracking

We adapted our automated feature tracker [Choi et al., 2007] to measure the zonal wind profile of Saturn’s atmosphere from VIMS cubes. Here, cloud features are assumed to act as passive tracers of the ambient zonal winds. However, instead of using hand and eye to track features in images separated by a discrete time, we use software to extract portions of an image and compare them to nearby portions of a later image. Our software then determines which portions have the highest correlation and measures their offset, which is then used to determine wind velocity. This technique has been used to measure winds of Jovian vortices [Vasavada et al., 1998; Read et al., 2005; Choi et al., 2007], eddy velocity fluxes on Jupiter and Saturn [Salyk et al., 2006; Del Genio et al., 2007], and Venusian atmospheric velocities [Toigo et al., 1994].

We examined five particular data sets (Table 1) out of more than twenty observation sequences that were designed for feature tracking. Unfortunately, we could not integrate the remaining data into our analysis because of poor observation geometry, map reprojection issues, poor image resolution, or a combination of all three. Our feature tracker normally attempts to measure velocities both in the zonal and meridional directions. However, we find no evidence of synoptic- or regional-scale meridional motion. Furthermore, the low spatial resolution of the VIMS data is insufficient for tracking local meridional motion. Thus, we modified our feature tracker to only measure zonal velocities. Subtle meridional shifts are apparent when manually blinking some images separated in time but are likely caused by uncertainties in camera pointing and image navigation. In addition, we adapted our feature tracker for the VIMS data by changing the size and shape of the correlation boxes that are extracted from the images. Small squares (the mode that our software typically uses) for correlation portions were unfit for the VIMS data as typical tracked cloud features were relatively large (a result of the low image resolution), and chances of returning a spurious result by the algorithm were high. We instead used correlation boxes that spanned a narrow range of latitudes (~1°) but the full range of longitudes available in the image. The technique returns a single zonal velocity for each latitude. The precise latitudinal location of each velocity vector is set at the midpoint latitude of each rectangular correlation box. Limaye [1986] used a similar technique to construct one of the first zonal wind profiles of Jupiter. Typical image separation times for VIMS cube frames that we analyzed range from 10 to 30 min.

The 1° latitude correlation box leads to a ~0.5° uncertainty for the vector’s location, since the vector could result from feature(s) anywhere within the box. We can estimate the effect that the locational uncertainty has on the velocity measurement by multiplying it by the magnitude of latitudinal wind shear. We estimate that the typical uncertainty is ~10 m s⁻¹, though it could be up to 30–40 m s⁻¹ in a high latitudinal shear environment. However, this is an upper bound to the uncertainty, as it is unlikely that the tracked features in a correlation box are all located at one edge of the box. Overall, the uncertainty in the zonal wind measurements is insufficient to significantly affect our conclusions.

3. Results

3.1. Atmospheric Features

Much like the southern hemisphere, near-infrared continuum filter mosaics composed from ISS analyzed by Vasavada et al. [2006], the VIMS mosaics (Figures 1, 2, and 3) exhibit a gradation with latitude in cloud feature clarity: the diffuse and muddled features in the lower latitudes contrast sharply with the more well defined, distinct features seen in higher latitudes. The relative lack
of well-defined, high-contrast features in the equatorial region supports the presence of an optically thick haze in the upper atmosphere capable of attenuating the thermal emission. However, occasional dark, wispy cloud features are visible in the equatorial region (Figure 4). These are likely clouds at deeper altitudes that perhaps erupt periodically and are more effective at blocking the thermal emission. Equatorial 5 μm hot spots similar to those encircling Jupiter [Ortiz et al., 1998; Arregi et al., 2006] have not been observed at low latitudes, a result noted previously by Yanamandra-Fisher et al. [2001] through ground-based telescopic observations.

The overall cloud morphologies in the VIMS and ISS mosaics are also broadly similar. The tropical latitudes in both hemispheres are dominated by numerous tilted, alternating dark and light linear features that strongly resemble the “tilted cloud streaks” noted by Vasavada et al. [2006] in their study. An especially strong wind shear environment (10 to 20 m s⁻¹ per degree of latitude) is present at these latitudes. Interspersed between the tilted features are zonally aligned light and dark stripes located at approximately 16°S, 22°S, 28°S, and 15°N. These bands span a wide range of longitudes but appear interrupted at some places and are not as distinct as the bands seen at higher latitudes. The region between 30°S–35°S is a transitional region containing both occasional spot features (including a few with spiral patterns surrounding them, suggesting circulation) and stripes (both light and dark) occasionally interrupted by ambient clouds. A pair of narrowly separated zonal jets at 31°S and 33°S are perhaps responsible for the complex meteorological patterns. A similar transition region containing two light stripes with ragged cloud features interspersed in between them is present between 30°N and 35°N. However, no known zonal jet exists at this latitude in the northern hemisphere.

The midlatitudes (poleward of 35° latitude) in both hemispheres of Saturn are notable for the presence of numerous compact dark spot features, indicating regions of high cloud opacity from their efficiency at blocking Saturn’s thermal radiation. The majority of these spots are singular and isolated, though many instances of complex structures (apparent mergers, possible interacting structures, and amorphous shapes) are present interspersed among the singular spots. As discussed in Section 3.3, these dark features are not distributed evenly across latitudes but instead concentrate in dense populations between distinct, zonally aligned stripes. These stripes correspond to locations of zonal jets (discussed further in Section 3.2), unlike the subtle bands seen in tropical latitudes, which are not associated with the jets. The image resolution and temporal...
coverage of the observations are insufficient for estimating the vorticity of these features, and we cannot definitively state how many of these spots are vortices.

[20] A salient feature of the northern hemisphere in the VIMS mosaics is the so-called “string of pearls” that exists in a narrow band just south of 40°N. These features are areas of uncharacteristically high thermal emission, indicative of low cloud opacity. We catalogued 22 “pearls” in the northern hemisphere mosaic, and examination of the central locations of these pearls reveals that they roughly divide into three groups. The first group of five and the second group of ten have similar spacings between pearls of about 3.7° longitude on average. However, the third group of seven are each spaced slightly wider, with a mean separation of approximately 4.8°. The shapes of the pearls are slightly elliptical, with a median aspect ratio (defined as east-west length divided by north-south length) of approximately 1.1. However, we note that there are some examples of pearls with shapes at both extremes, with aspect ratios ranging from 0.5 to 1.7.

[21] Two possible analogues currently exist for these features. Our preferred hypothesis is that the pearls are a manifestation of a von Kármán vortex street, a repeating pattern of vortices where cyclones and anticyclones alternate with one another. The contrasting regions of cloud opacities could correspond to alternating regions of relative vorticity, with 5 μm bright regions being cyclonic and dark regions being anticyclonic. The proximity of the pearls to 40°N, a quasi-westward flowing band wedged between strongly eastward flowing jets (see Figure 5) supports the vortex street model. The White Ovals, a system of anticyclones thought to be part of a von Kármán vortex street on Jupiter [Youssef and Marcus, 2003], were located in a similar position in Jupiter’s zonal wind profile (a westward flowing band in between two eastward jet streams). We again caution that we cannot directly measure the local wind flow of these features and thus cannot confirm that they are vortices. However, preliminary numerical simulations of Saturn’s midlatitude atmosphere support our hypothesis of a vortex street model for the pearls (K. Sayanagi, personal communication, 2008). An alternative possibility is that these areas of enhanced emission result from cloud modulation caused by wave motion, similar to the 5 μm equatorial hot spots on Jupiter, though the “pearls” appear to be more numerous and smaller than their Jovian counterparts. Whereas equatorial hot spots on Jupiter range in length from 5,000 to 10,000 km [Orton et al., 1998], the average length of a pearl on Saturn is just over 1,000 km. Another contrast between the two features is the observation that there are typically ~10 Jovian 5 μm hot spots that globally span the latitude band between 5°N and 10°N [Arregi et al., 2006]. In contrast, Saturnian pearls appear to be confined to a span of latitude approximately 10° in width, and are more numerous. The leading explanation for Jovian hot spots is that they are a manifestation of the downwelling branch of an equatorially trapped Rossby wave [Allison, 1990;
Figure 3. VIMS northern hemisphere mosaic. Saturn’s northern hemisphere as seen by VIMS in the 5 μm spectral window. This mosaic is an assembly of images taken in April 2006.

Figure 4. Rectangular projection of VIMS data cubes in the 5 μm spectral window observing the northern tropical latitudes. The time separation of these two images is 29 min, 22 s.
3.2. Zonal Wind Profile

[22] Figure 5 is our constructed zonal wind profile. For comparison, we have also included the zonal wind profiles constructed from Voyager [Sánchez-Lavega et al., 2000] and Cassini [Vasavada et al., 2006] imaging data. Generally, our zonal wind profile is in excellent agreement with the shape of previous zonal wind profiles from Voyager and Cassini and with previous preliminary reports about the VIMS data set [Baines et al., 2005a], indicating that the overall jet structure has remained broadly consistent. An additional work by Baines et al. [2005b] states a measurement of 390 ± 50 m s⁻¹ for a feature at 8°S, which is in agreement with our results. The broad equatorial jet is clearly evident, and its latitudinal shear is also in reasonably good agreement with previous zonal wind profiles. Our analysis of the VIMS images provides evidence for rapid equatorial flow at the jet core: clouds just north of the equator flow at ~500 m s⁻¹, and perhaps even faster. This suggests that the near factor of 2 reduction in speed relative to Voyager measurements for the equatorial jet [Sánchez-Lavega et al., 2003] and the more modest reduction measured by Porco et al. [2005] could perhaps be confined to the upper troposphere and that VIMS may be sensing deeper levels of the jet at these latitudes. We express caution with these particular measurements of rapid flow at the jet core (i.e., the cluster of points with \( u > 500 \) m s⁻¹ at ~1–5°N and 7°S), as the equatorial region typically lacks discrete, high-contrast cloud features that are easily trackable by our technique. However, we have performed manual cloud tracking of a small cloud complex embedded in the flow (seen earlier as Figure 4) that support the measurements above 500 m s⁻¹. We note that it is possible that the highest-speed, tracked cloud features are a local disturbance and not characteristic of the zonally averaged flow. Regardless, it seems clear that the equatorial jet speed exceeds ~400–450 m s⁻¹ at the pressure sensed by VIMS 5 μm images.

[23] A few higher-latitude jets are present in the VIMS data, though unfortunately we cannot derive results south of 60°S using our current techniques on the publicly available data set. There is remarkably good agreement among all three zonal wind profiles for the precise latitudinal location of the jets. However, differences exist in the peak speeds measured at the jet cores, with the exception of the jet near 45°N, where our derived speeds from VIMS is nearly identical to that from Voyager. Furthermore, there is no universal increase or decrease of the peak velocities across all jets between the VIMS profile and past profiles. The jet cores at 75°N and 50°S appear to be flowing faster than in the previous profiles. The measurement at 75°N is attributed to a cluster of clouds located north of a large dark spot feature, and these clouds appear to be embedded in a relatively wide westward flowing jet. At 50°S, a cloud feature that is embedded in a dark stripe (presumably corresponding to a narrow jet stream) is the likely source for our measurement. Though manual inspection of these features support our automated measurements, it is important to note that it is unclear how closely the motion of these features represent the ambient zonally averaged zonal flow. The measurement at 60°S also supports the presence of apparent wind shear compared with past profiles, though we feel this measurement is less convincing from lack of repeat observations. One of the starkest differences between the VIMS zonal wind profile and previous profiles is the jet at 65°N, which appears to be flowing at nearly half of the speed of the jet at that latitude as seen by Voyager. Upon further manual inspection of the feature tracking images at that latitude, the evidence for wind shear at this location is inconclusive because of the low image resolution.

3.3. Spot Feature Statistics

[24] Our database of spot features consists of 578 and 572 entries for the two southern hemisphere mosaics, and 297 entries for the northern hemisphere. For the purposes of comparison, we have also analyzed the southern hemisphere ISS mosaic composed and examined by Vasavada et al. [2006, Figure 1]. This mosaic is composed of images observed using one of the near-infrared (750 nm) continuum filters. We only analyze the compact, patchy, light spots (clouds) in the ISS mosaic, as Vasavada et al. [2006] have already reported their analysis on the darker vortices. (It is important to note here that features that appear dark in VIMS 5 μm images are simply more effective at blocking the thermal emission, whereas features that appear dark in ISS images are inherently lower in albedo.) We catalogued 687 light spots in the ISS mosaic, and used the same ISIS analysis tools throughout all four mosaics.

Figure 5. Zonal wind profile for Saturn’s atmosphere constructed from an automated feature tracker analysis of VIMS data. Our VIMS results are shown as small, black dots. For comparison, two other profiles are shown, the Voyager profile [Sánchez-Lavega et al., 2000] and the Cassini ISS profile [Vasavada et al., 2006]. Uncertainties for the VIMS measurements are ~10 m s⁻¹ and are dependent on the amount of latitudinal wind shear around the measurement.
Figure 6 is a histogram showing the number of spot features as a function of latitude (planetographic). (a) VIMS southern hemisphere mosaic I. (b) VIMS southern hemisphere mosaic II. (c) ISS southern hemisphere mosaic, captured during the first orbit of Cassini around Saturn in 2004. The unfilled areas are light spots analyzed in this current study, whereas black bars are dark, low-albedo spot features analyzed by Vasavada et al. [2006]. (d) VIMS northern hemisphere mosaic.

Figure 6 is a histogram showing the number of spot features as a function of their latitude for all four of the mosaics that we have analyzed. We sorted the features into latitude bins 1° in size, centered at each integer latitude. The histograms for the southern hemisphere VIMS mosaics (Figures 6a and 6b) demonstrate that the features are primarily located in three bands that are demarcated by zonal jet streams. The latitudinal distribution of these features is remarkably similar in the two mosaics, with minor differences between the two mosaics attributable to irregularities in observational coverage and inherent variability in the populations and lifetimes of these features. A fourth band containing spot features is suggested at higher latitudes (>75°S). However, because of the poor image resolution and the cutoff in the image beyond 80°S, we are probably under-representing the population of features in this latitude band.

Figure 6c is the number distribution of the light, high-albedo spots in the ISS mosaic as a function of latitude. For comparison, we have included the population of the dark, low-albedo spot features counted by Vasavada et al. [2006] as black segments to supplement our results. The features are clearly divided into four latitudinal zones largely similar to the distribution seen in our southern hemisphere VIMS mosaics, with some differences in the number of features seen in each latitude zone between the ISS and VIMS mosaics. South of 50°S, we detect more features in the ISS mosaics than in the VIMS mosaics, with substantially more in the southern polar regions. This is likely a result of improved image resolution and facilitated feature identification at the higher latitudes in the ISS images (rather than incomplete longitudinal coverage, as we will show in Figure 7).

Figure 6d is the number distribution of dark spots in the northern hemisphere VIMS mosaics. The tropical latitudes contain occasional spots, with the numbers increasing gradually with latitude. A main group of spots is centered poleward of 40°N, with a secondary group of spots present spanning 52°–59°N. A broad gap in the spot population at 45°–50°N aligns with a strong prograde jet at that latitude band. This matches the basic structure seen in the southern hemisphere, where zonal jets mark latitudes with a deficiency of spots. However, this structure does not extend to
the tropical latitudes, as gaps in the population distribution exist on the flank of the fast equatorial jet.

The histograms shown in Figure 6 are simply the number of spots that occur in latitude bins 1° wide, as a function of latitude, in our mosaics. However, our longitudinal coverage varies from latitude to latitude; moreover, the circumference of any given latitude circle decreases with increasing latitude. It is thus useful to normalize the spot numbers to remove these effects. To do so, we calculate the number of spots \( N \) that occur in latitude bins 1° wide per unit longitudinal distance. This is given by

\[
N = \frac{N}{2\pi f R_{\text{curv}}}.
\]

where \( N \) is the number of spots in a latitude bin, \( f \) is the fraction of mosaic coverage at that latitude (unitless), and \( R_{\text{curv}} \) is the zonal radius of curvature. Figure 7 shows this quantity for all four mosaics. Because \( N \) compensates for the gaps in the VIMS mosaic coverages, any remaining differences between Figures 7a and 7b and Figure 7c suggest that other factors account for the discrepancies in the spot counts. The larger normalized count in the ISS mosaic at high latitudes (poleward of 60°S) compared to the VIMS counts in these bands is likely caused by improved image resolution in these areas. The smaller normalized count in the ISS mosaic at midlatitudes (37°S–48°S) is more puzzling. This could be indicative of increased activity or a more complex vertical structure confined to these latitudes.

Figure 8 presents a number-size distribution for all four mosaics, including the spot feature population in the paper by Vasavada et al. [2006]. The overwhelming majority of the spot features are below 1500 km in east-west diameter. However, a few features have diameters that exceed 2000 km, with one feature in both southern hemisphere VIMS mosaics exceeding 5000 km diameter. The ISS southern hemisphere distribution (Figure 8c) reveals a slight difference in the location of the peak size. Whereas the VIMS southern hemisphere size distribution peaks at about 600 km, the ISS distribution peaks at a lower size, about 400 km. This may be an artifact of enhanced resolution in the ISS mosaics and as a result, improved detectability of the smallest features. The peak in the size distribution at 400–600 km has implications for Saturn’s Rossby radius of deformation, a length scale at which rotational (Coriolis) effects become comparable to buoy-
ancy effects. One can expect vortices at a size near the deformation radius, as structures that develop from inverse energy cascade and geostrophic adjustment typically attain sizes near this length scale [Cho and Polvani, 1996; Polvani et al., 1994]. If we assume that the majority of this population are small vortices, it suggests that the deformation radius is within a factor of 2 of \( \frac{\mu_{24}}{C_{24}} \approx 500 \) km. This estimate is relatively small compared to estimates of the deformation radius on Jupiter (Showman [2007] reports 1000–3000 km on the basis of his numerical simulations) and in the upper troposphere of Saturn (2000–8000 km from Read et al. [2007] via an analysis of the zonal wind, temperature, and molecular hydrogen para-fraction profile).

[30] We examine a feature’s east-west diameter as a function of its latitude in Figure 9 and Table 2. Clearly, most of the spot features are below 1500 km in diameter, with few features above this threshold. We note a subtle decrease in the characteristic diameters of the features with increasing latitude in both hemispheres. This slight trend also suggests that the deformation radius is a controlling factor in the formation of these spot features. The deformation radius is inversely correlated with the Coriolis parameter \( f \); therefore, the radius will decrease with higher latitude.

[31] Figure 10 presents the aspect ratios for all of the features catalogued in our study. We define aspect ratio as the ratio of a feature’s principal east-west diameter to its principal north-south diameter. Most of the features span a broad range of aspect ratios, as there is no obvious bias toward a particular shape for these features in the main population below 1500 km diameter. However, we note that larger features (>2000 km) exhibit a preference for an aspect ratio greater than unity (zonal elongation). Aspect ratios for visible spots have been measured before on Jupiter and Saturn. Mac Low and Ingersoll [1986] noted that aspect ratios tended to be greater than unity with increasing east-west diameters on the basis of their analysis of spots on Jupiter from Voyager imagery. Li et al. [2004] demonstrate the same trend on the basis of their analysis of Jovian spots from Cassini imagery. Both studies reveal that spots on Jupiter with diameters above 3000 km tend to be more zonally elongated. Saturn appears to also follow this general rule. Vasavada et al. [2006] also show that the dark, low-albedo vortices on Saturn tend to have aspect ratios greater than unity, though we note that from both Saturn studies, there is a general deficiency in the feature population above 3000 km compared with the population found in Jupiter’s atmosphere. This property of the features in

[2006]. (d) VIMS northern hemisphere mosaic.
both Jupiter’s and Saturn’s atmospheres may be a manifestation of the β-effect (the variation of the Coriolis force with latitude) acting to preferentially elongate structures that exceed a diameter of ~2000 km.

4. Discussion

[32] Bjoraker et al. [2007] estimates that the 5 μm thermal radiation emanates from a pressure level of 5 bars. However, the depth at which the thermal radiation originates does not necessarily have to coincide with the depth of the imaged features in the VIMS mosaics. Preliminary radiative transfer analysis by Baines et al. [2005a] and Momary et al. [2006] indicate that the features observed by VIMS are near the 2 bar level. Utilizing information gleamed from the ISS and VIMS zonal wind profiles, assuming that they originate from different depths, yields constraints about the latitudinal temperature gradient of Saturn’s atmosphere. Saturn’s winds are in geostrophic balance, and vertical shear of geostrophically balanced winds is controlled by the thermal wind equation [Holton, 2004]

\[
\frac{\partial \mathbf{v}_g}{\partial p} = \frac{R}{\rho f} \mathbf{k} \times \nabla T,
\]

where \( \mathbf{v}_g \) is the geostrophic wind, \( p \) is pressure, \( R \) is the specific gas constant, \( f \) is the Coriolis parameter, and \( T \) is the temperature. Thus, with all other factors being equal, vertical shear in the geostrophic zonal winds is directly tied to the latitudinal temperature gradient.

correlated with the latitudinal gradient of temperature. If we assume that the features tracked by ISS and VIMS are separated by a scale height, we can place a bound on the vertical wind shear using the uncertainty in the zonal wind profile. Using our uncertainty estimate of ±10 m s\(^{-1}\) \(\partial T/\partial y\) has an upper bound of \(\sim0.5^\circ\)K per 1000 km. When extrapolated over 5,000–10,000 km, our zonal wind profile rules out latitudinal temperature contrasts exceeding 2–5\(^\circ\)K throughout most of the atmosphere.

However, apparent wind shear is present at certain jet stream cores. Our zonal wind profile shows faster wind speeds at the equator and at the 48\(^\circ\)S jet core compared with previous profiles. Recently, Sánchez-Lavega et al. [2007] used methane and near-infrared filter images from Cassini ISS, and observed higher-altitude features flowing at a slower speed compared to features at the main cloud deck (\(~700\) mbar), yielding a vertical wind shear \(\partial u/\partial z\) \(\sim40\) m s\(^{-1}\) per atmospheric scale height \(H\) (\(\sim50\) km at the equator). García-Melendo et al. [2009] has extended that work to show that vertical wind shear (estimated at 10 m s\(^{-1}\) per atmospheric scale height \(H\)) is present at several southern hemisphere zonal jets. However, if we again assume that the features tracked by ISS and VIMS are separated by a scale height, the \(\sim100\) m s\(^{-1}\) difference at the jet cores implies a shear that is greater than the estimate from Sánchez-Lavega et al. [2007] by a factor of 2–3. (Our wind shear is also well above the \(\sim25\) m s\(^{-1}\) per atmospheric scale height at the 500 mbar level estimated by Flasar et al. [2005].) Importantly, our VIMS cloud tracking, coupled with ISS cloud tracking results, allows us to

![Figure 10](image-url)
constrain the latitudinal temperature gradients at pressures significantly deeper than that directly measurable from thermal-emission spectra with, for example, Cassini’s Composite Infrared Spectrometer (CIRS) [Flasar et al., 2004]. Our measured vertical wind shear implies a local latitudinal temperature gradient at the 2 bar level to be \( \sim 1^\circ \text{K per 1000 km} \) at the equator, and as high as \( \sim 5^\circ \text{K per 1000 km} \) at the 48\(^\circ\)S jet. Our estimates are upper bounds, as shear would be lower if VIMS were observing features in a deeper (>2 bar) cloud deck. Thus, our analysis implies that the latitudinal temperature gradients at specific latitudes may exceed gradients found at other latitudes at the same pressure.

[34] From our analysis of the cloud features in the VIMS and ISS mosaics, it appears plausible that VIMS is simply observing the same cloud features that have been observed by visible imagers from Cassini and Voyager. Figure 11 (left) is a portion of an ISS mosaic analyzed by Vasavada et al. [2006], whereas Figure 11 (right) is an inverted portion of Figure 1, one of the southern hemisphere VIMS mosaics. Note the general similarities between both mosaics in the alignment of the horizontal stripes, the bright, white cloud features at higher latitudes, and the possible long-lived vortex just north of 60\(^\circ\)S. The appearance of the stripes at higher latitudes also match well, indicating that the high-albedo, white bands (suggestive of a thick cloud band) observed in ISS images are dark in the 5 \( \mu \)m images (indicating high opacity), and dark bands are bright in the 5 \( \mu \)m data set (indicating low opacity).

[35] Comparison of the statistics of the spotted features in the VIMS and ISS mosaics also suggests that both instruments are typically observing the same features. Similarities in the features’ latitudinal distribution and numerical population are evidence that the majority of the VIMS dark spots are white cloud patches seen in the ISS images. These bright cloudy areas likely contain abundant aerosols that are efficient at blocking abyssal thermal radiation. Unfortunately, this creates a degeneracy for the VIMS dark spots as both the patchy white clouds and the dark, low-albedo vortices contribute to the VIMS dark spot population. One key difference based on Figure 8 is that features analyzed by Vasavada et al. [2006] that exceed 1000 km diameter seem to be largely missing in the VIMS mosaics, as only a small percentage of VIMS features have diameters above this threshold. However, we note that on the basis of Figure 8 of Vasavada et al. [2006], most of the dark vortices in the ISS images with diameters below 1000 km are simply classified as “dark.” In contrast, most of the ISS vortices with diameters above 1000 km are classified as “dark with bright margin,” “bright centered,” or simply “bright.” Thus, it is possible that these more complex vortex families have a different structure when observed in 5 \( \mu \)m and were overlooked in our analysis.

[36] Overall, we believe that the majority of the dark spotted features seen in the VIMS mosaics are the same features as the ubiquitous white and dark spots seen in ISS images. In one scenario, ISS and VIMS could simply be...
observing the same cloud layer; lateral modulation of that cloud deck would then produce lateral variations in reflected sunlight (hence producing the ISS features) as well as lateral variations in 5 μm emission to space (hence producing the VIMS 5 μm features). However, estimates of the altitudes of features observed in ISS are ~700 mbar, which is substantially less than that suggested for the depth of the VIMS features (~2 bars). Alternatively, we propose a scenario where ISS is observing the reflected cloud tops of an ammonia cloud feature aloft, and VIMS is observing the base of this cloud feature at depth. This scenario implies that the features are nearly a scale height (or more) in thickness. For this scenario to work, the upper level cloud tops that cause reflection of short-wavelength sunlight (as observed by ISS) must have small enough particle size so that they do not block the 5 μm radiation upwelling from deeper levels. One thus needs a vertical gradient in particle size, with smaller particles aloft and larger particles at the base. The cloud structure associated with a given feature (e.g., a vortex) could thus cause reflection of sunlight from pressures of <1 bar while allowing emission of 5 μm radiation from ~2 bars. In any scenario, however, we must remain careful in interpreting the structure of Saturn’s atmosphere at the jet streams, as VIMS may be observing tracers of motion housed in a deeper NH₃SH, or perhaps H₂O cloud deck.

[37] Though we have not directly observed rotation within these spot features, we believe that these spots are vortices. Our analysis suggests that the deformation radius of Saturn’s atmosphere controls both their inherent size and the variance of their size with latitude. Furthermore, Penny et al. [2008] suggest that the Rhines effect [Rhines, 1975] is suppressed at the latitudes containing VIMS spot features, indicating that these latitudes can generate and support vortices. Our proposed hypothesis that the spots have finite thickness is also consistent with the dynamics of coherent vortices; the vertical extent of such a feature is typically f/N times their horizontal width, where f is the Coriolis parameter and N is the Brunt-Väisälä frequency [Charney, 1971; Reinard et al., 2003]. For Saturnian estimates (f ~ 10⁻⁴ s⁻¹ and N ~ 0.001–0.005 s⁻¹) a vortex 1000 km across would then be 20–100 km or 0.5–3 scale heights thick. Moreover, numerical models of vortex evolution show success in matching vortex observations when the vortices are 1–3 scale heights thick [Morales-Juberias and Dowling, 2005].

5. Summary and Future Work

[38] We have performed an analysis of an extensive data set about the Saturnian atmosphere in the 5 μm spectral window from the VIMS instrument on board Cassini. Our mosaics of both the northern and southern hemispheres reveal an extensive population of dark, compact spots that are areas of blocked thermal emission. A statistical analysis of these features and comparison with earlier visible light mosaics of the southern hemisphere suggest that the majority of the ordinary spot features seen in the VIMS mosaics are white cloud patches, with a minority population of dark (in reflected sunlight) vortices. Automated cloud feature tracking reveals that the general structure of the zonal wind profile is largely similar to profiles constructed from Voyager and Cassini data. Differences in the speeds exist at some latitudes, indicative of longitudinal variability or observation of deeper features indicating vertical wind shear.

[39] Many opportunities are available for continued analysis of the rich VIMS data set concerning Saturn’s atmosphere. Further radiative transfer studies will help constrain the altitudes of the features observed by VIMS and refine our estimates of the vertical wind shear and temperature gradients in the atmosphere. Analysis of features at polar latitudes was beyond the scope of this study, but interesting features are located at these latitudes, including a polar vortex above the south pole and a hexagonal standing wave above the northern polar regions [Baines et al., 2007]. Cassini’s extended mission will yield an opportunity to measure seasonal changes in the chemistry, meteorology, and structure of the atmosphere. Additional observation sequences designed for feature tracking will allow us to supplement our zonal wind profile and measure the degree of vertical wind shear throughout all latitudes. Furthermore, the majority of the VIMS data that we have analyzed are observations of the night side of Saturn, preventing us from comparing simultaneous VIMS and ISS images for common features. Comparative studies of the ISS and VIMS data sets and future planned observations will test vertical cloud structure models. We look forward to continued analysis of the data returned by VIMS and the Cassini spacecraft as we continue to explore Saturn’s unique atmosphere.

[40] Acknowledgments. We thank our reviewers, Ashwin Vasavada and Andrew Ingersoll, for providing helpful comments that strengthened this paper. We thank Dyer Lytle and Virginia Pasek for their assistance in this project. We also thank Joe Plassmann and the staff of the Planetary Image Research Laboratory at the University of Arizona for their assistance and maintenance of some of the computing resources used for this research. We thank Ashwin Vasavada and Sarah Horst for providing us with the ISS mosaic analyzed in this paper and their data. This research was supported by NASA Headquarters under the NASA Earth and Space Science Fellowship Program grant NNX08AW01H, NASA Planetary Astrophysics grants to A.P.S., the Cassini program, and the University of Arizona TRIF Imaging Fellowship.
